#### Data 8 Final Study Guide — Page 1

```
Higher-order function: A function that returns a function
def <name>(x):
    def <inner name>(y):
        return <some expression involving x and y>
    return <inner name>
```

The returned *function* takes one argument ( $_{y}$ ) but computes its result from two values ( $_{x}$  and  $_{y}$ ).

The regression line is the one that minimizes the (root) mean squared error of a collection of paired values

The slope and intercept are unique for linear regression
 def mean squared error(table, x, y):

```
def mean_squared_error(table, x, y):
    def for_line(a, b):
        estimate = (a * table.column(x) + b)
        return np.average((table.column(y) - estimate) ** 2)
    return for_line
long = faithful.where('eruptions', are.above(3))
mse_long = mean_squared_error(long, 1, 0)
a, b = minimize(mse_long) # regression line is a * x + b
```

Simple regression: one input → one output

Multiple regression: many inputs → one output

GPA = a<sub>days</sub> \* days + a<sub>contributions</sub> \* contributions + b

We could find a's and b by minimizing mean squared error

**Inference**: Making conclusions from random samples **Population**: The entire set that is the subject of interest **Parameter**: A quantity computed for the entire population **Sample**: A subset of the population

In a **Random Sample**, we know the chance that any subset of the population will enter the sample, in advance **Statistic**: A quantity computed for a particular sample

Estimation is a process with a random outcome

Population (fixed)  $\rightarrow$  Sample (random)  $\rightarrow$  Statistic (random) A 95% **Confidence Interval** is an interval constructed so that it will contain the parameter for 95% of samples For a particular sample, the interval either contains the parameter or it doesn't; the process works 95% of the time **Resampling**: When we wish we could sample again from the population, instead sample from the sample

The 80th percentile is the value in a set that is at least as large as 80% of the elements in the set

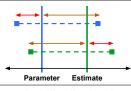

```
For s = [1, 7, 3, 9, 5], percentile (80, s) is 7
The 80th percentile is ordered element 4: (80/100) * 5
```

For a percentile that does not exactly correspond to an element, take the next greater element instead

```
percentile(10, s) is 1 percentile(20, s) is 1 percentile(21, s) is 3 percentile(40, s) is 3
```

If an interval around the parameter contains the estimate, then a (reflected) interval of the same width around the estimate contains the parameter (and vis versa)

#### K-nearest Neighbor classifier

**Goal**: Using a set of labeled examples, define a classifier that can predict the label of an unlabeled example **Example**: A set of features (i.e., a row in a table of features)

**Example**: A set of features (i.e., a row in a table of features) **Data preparation**: *Randomly* divide all available examples into three sets: training, validation, and test

**Classification:** Find the K examples in the training set that are most similar to the example and average the labels **Accuracy:** The proportion of examples in a set (e.g., the test

**Accuracy:** The proportion of examples in a set (e.g., the test set or validation set) that are classified with the correct label

```
def distance(pt1, pt2):
    tot = 0
    for i in range(len(pt1)):
        tot = tot + (pt1[i] - pt2[i])**2
    return math.sqrt(tot)
def computetablewithdists(training, p):
    dists = np.zeros(training.num_rows)
    attributes = training.drop('Class')
    for i in np.arange(training.num_rows):
        dists[i] = distance(attributes.row(i), p)
    return training.with_column('Distance', dists)
def closest(training, p, k):
    withdists = computetablewithdists(training, p)
    sortedbydist = withdists.sort('Distance')
    topk = sortedbydist.take(np.arange(k))
    return topk
def majority(topk):
    if topk.where('Class',1).num_rows>topk.where('Class',0).num_rows
    else:
        return 0
def classify(training, p, k):
    closestk = closest(training, p, k)
    topkclasses = closestk.select('Class')
    return majority(topkclasses)
def evaluate_accuracy(training, test, k):
    testattrs = test.drop('Class')
    numcorrect = 0
    for i in range(test.num rows):
        # Run the classifier on the ith patient in the test set
        c = classify(training, testattrs.rows[i], k)
        # Was the classifier's prediction correct?
        if c == test.column('Class').item(i):
            numcorrect = numcorrect + 1
    return numcorrect / test.num rows
```

#### Feature Selection Using the Validation Set

Goal: Select features and K to maximize accuracy

**Overfitting**: Accuracy is higher on the set used for feature selection than another set because of peculiarities of the set

**Selecting Features:** Maintain a set of selected features, which starts out empty; Each added feature is the feature that improves validation set accuracy the most, in combination with the features already added

### Data 8 Final Study Guide — Page 2

#### Total Variation Distance (TVD):

- For each category, compute the difference in proportions between two distributions
- Take the absolute value of each difference
- Sum and divide by 2

def total\_variation\_distance(column, other):
 return sum(np.abs(column - other)) / 2

np.random is a collection of sampling procedures

np.random.randint(lower, upper)

An integer lower bound (inclusive)

An integer upper bound (exclusive)

np.random.multinomial(n, distribution)

The number of samples to draw

An array or list containing the chance for each category

# Does a sample look like a random sample from a distribution?

- E.g., Do the counts of races on a jury panel look like a random sample from the proportion of races in a county?
- Sample many times from the distribution and compute the TVD of each sample from the original distribution
  - o The result is called an empirical distribution of a statistic
  - o It approximates the sampling distribution of the statistic
- Compare the observed TVD between the sample and the original distribution to this empirical distribution

def empirical\_distribution(table, label, size, k, f):
 stats = Table(['Sample #', 'Statistic'])
 for i in np.arange(k):
 sample = table.sample\_from\_distribution(label, size)
 statistic = f(sample)
 stats.append([i, statistic])
 return stats

# Step 1: The Hypotheses

- A test chooses between two views of how data were generated
- Null hypothesis proposes that data were generated at random
- Alternative hypothesis proposes some effect other than chance

# Step 2: The Test Statistic

• A value that can be computed for the data and for samples

# Step 3: The Sampling Distribution of the Test Statistic

- What the test statistic might be if the null hypothesis were true
- Approximate the sampling distribution by an empirical distribution

# Step 4: Resolve choice between null and alternative hypotheses

- Compare observed test statistic to its empirical distribution under the null hypothesis
- If the observed value is consistent with the distribution, then the test does not support the alternative hypothesis

**P-Value**: The chance, under the null hypothesis, that the test statistic is equal to the value that was observed or is even further in the direction of the alternative.

**Statistically Significant:** The P-value is less than 5% **Highly Statistically Significant:** The P-value is less than 1%

### Comparing samples: Do two groups differ in some attribute?

- E.g.: Among U.S. men who are in heterosexual relationships, is there an association between marriage and employment status?
- Null hypothesis: In the United States, the distribution of employment status among married men is the same as among unmarried men who live with their partners.
- Inferential Idea: If marital status and employment status were not connected in any way, then we could replicate the sampling process by replacing each man's employment status by a randomly picked employment status from among all the men
  - o Permute (shuffle) the outcome column K times ------
  - o A shuffled table pairs each example with a random outcome ---
  - Compute the total variation distance between the two treatment conditions to create an empirical distribution

#### Bootstrap A/B test using means

- *n* individuals in Category A; *m* in Category B
- Under the null hypothesis, samples in both categories are drawn from the same underlying distribution.
- So draw (n+m) times at random with replacement from the entire sample. Assign n of the draws to Category A and m to Category B.
- Find the difference between the means of these two new groups.
- Repeat the last two steps many times and compare with the difference between the two original sample means.

We observed a positive slope and used it to make our predictions.

But what if the scatter plot got its positive slope just by chance?

What if the true line is actually FLAT?

- Bootstrap the scatter plot & find the slope of the regression line through the bootstrapped plot many times.
- Draw the empirical histogram of all the resampled slopes.
- Get the "middle 95%" interval: that's an approximate 95% confidence interval for the slope of the true line.
- Null hypothesis: The slope of the true line is 0.
  - Construct a bootstrap confidence interval for the true slope.
  - o If the interval doesn't contain 0, reject the null hypothesis.
  - If the interval does contain 0, there isn't enough evidence to reject the null hypothesis.
- **Residual**: Difference between y and regression line height at x.
- Regression Model: y is a linear function of x + normal "noise"
- Residual plot looks like a formless "noise" cloud under this model
- Average of residuals is always 0 for any scatter diagram

 $|r| = \frac{\text{SD of fitted values of } y}{\text{SD of observed values of } y}$  SD of residuals  $= \sqrt{1 - r^2} \times \text{SD of}$ 

- Experiment: An occurrence with an uncertain outcome
- Outcome: The result of an experiment
- Sample Space: The set of all possible outcomes for the experiment
- Event: A subset of possible outcomes that have some property of interest
- Probability: The proportion of experiments for which the event occurs
- **Distribution**: The probability of all events

Multinomial distributions have a finite sample space

- Distribution with a fixed number of possible outcomes
- All outcomes are mutually exclusive for an experiment
- The sum of the chances of the outcomes is 1
- The probability of an event is the sum of the chances of the outcomes in which the event occurs

Conditional Probability: The chance of an event B given an event A Both events describe the same experiment & sample space

- Find all outcomes in which A occurs
- Divide the chances of A's outcomes by P(A)

Conditional Distribution

Find all outcomes in which B also occurs

- Sum the updated chances of these outcomes: P(B | A) = P(A, B) / P(A)
- Bayes' Rule: P(A | B) = P(B | A) \* P(A) / P(B)

```
repetitions = 500
tvds = Table().with_column("TVD between married and partnered men", [])
for i in np.arange(repetitions):
   # Construct a permuted table
   shuffled = males.select('Employment Status').sample()
  --combined = Table().with columns([
           "Marital Status", males.column('Marital Status'),
            "Employment Status", shuffled.column('Employment Status')])
   employment_shuffled = combined.pivot('Marital Status', 'Employment Status'
   # Compute TVD
                                                                      Randomly
   e s = employment shuffled
                                                                       permute
                                                                       (shuffle)
   married = e_s.column('married')/sum(e_s.column('married'))
                                                                       column y
   partner = e_s.column('partner')/sum(e_s.column('partner'))
   permutation_tvd = 0.5*sum(abs(married - partner))
   tvds.append([permutation_tvd])
```
